Keywords: Software Engineering, Spatial Modeling, Cyber-physical Systems.

Abstract: We present a method to engineer the control software of transport systems and analyze their safety using the Reactive Blocks framework. The development benefits from the model-based approach and makes the analysis of the systems at design time possible. The software is analyzed for freedom of collisions and other spatiotemporal properties by combining test runs of already existing devices to find out their physical constraints with the analysis of simulation runs using the verification tool BeSpaceD. This allows us to discover potential safety hazards already during the development of the control software. In particular, we introduce a methodology for the engineering and safety analysis of transportation systems and elaborate its practical usability by means of a demonstrator based on Lego Mindstorms.

1 INTRODUCTION

In the development of control software for transport and other cyber-physical systems, safety is a major challenge to achieve (Lee, 2008). Particularly, one has to analyze the software for compliance with spatiotemporal properties like guaranteeing a sufficient safety distance between devices at all times. This is mostly achieved by intensive and costly testing of the software for functional and quality of service attributes. To ease the analysis effort, we supplement traditional test-based development by applying a model-based software engineering technique. Its formal semantics facilitates the use of automatic model-checking and provers that can detect flaws in the control software. Since we perform the checks on the models and not on the later code, these flaws, which might be sources for violations of spatiotemporal properties, are discovered early making the overall development process more cost effective than plain system testing.

As a model-driven development tool, we chose Reactive Blocks (Kraemer et al., 2009). It provides the ability to reuse and share building blocks. Further, Reactive Blocks enables us to simulate data and control flows, to model check the building blocks for functional correctness, and to create executable code automatically. Moreover, we use BeSpaceD (Blech and Schmidt, 2014), which enables the verification of

spatiotemporal properties in safety-critical systems. It has been deployed in several applications implemented with Reactive Blocks and simulated in the Java software environment, e.g., (Han et al., 2015; Herrmann et al., 2016).

A contribution of this paper is a methodology that defines the various engineering and analysis steps of the control software development process. It allows us to combine the analysis of kinematic behavior and other data obtained by gauging existing devices with the simulation and formal verification of the control software in order to guarantee that a device fulfills certain spatiotemporal properties. An example for measured data is the worst-case braking distance of a train that is observed by testing an actual unit. It is directly considered in a BeSpaceD verification proving that the control software causes the train to brake sufficiently early such that collisions with other trains are prevented.

We apply the methodology by developing the control software of a demonstrator which is built with Lego Mindstorms together with additional sensors and servers. Lego Mindstorms offers the necessary hardware components needed to build a physical autonomous rail-based system. It is an affordable way to create demonstrators such as robots, that can be used in hobby settings as well as research. Event-driven software can be run on the Lego Mindstorms components enabling the control entities to execute actions

based on input received from the different types of sensors. We describe the Lego Mindstorms demonstrator as well as the various development steps following the methodology.

Reactive Blocks and BeSpaceD are introduced in Sect. 2 followed by the presentation of the methodology in Sect. 3. In Sect. 4, the demonstrator is discussed while Sect. 5 describes the development of its software based on the methodology. Section 6 refers to experience with the approach and in Sect. 7 we present related work. In Sect. 8, we conclude and name some ideas for future work.

2 REACTIVE BLOCKS AND BESPACED

The model-driven engineering technique Reactive Blocks is a tool-set for the development of reactive software systems (Kraemer et al., 2009). A system model consists of an arbitrary number of *building blocks*, i.e., models of subsystems or sub-functionalities, that are composed with each other. A major advantage of this modeling method is its reuse potential since a building block can comprise sub-functionality that is useful in many different applications. The building block is specified once, stored in a tool library, and, when needed, moved into a system model by simple drag and drop. The behavior of a building block is modeled by UML activities that may contain UML call behavior actions representing its inner building blocks. These inner blocks are also specified by UML activities such that the approach scales. The interface of a building block is specified by an *External State Machine* (ESM) that describes the abbreviated interface behavior of the block (Kraemer and Herrmann, 2009). To make analysis of functional correctness by model checking possible, the activities and ESMs are supplemented with formal semantics (Kraemer and Herrmann, 2010). Moreover, Reactive Blocks enables the automatic transformation of system models into well-performing Java code (Kraemer et al., 2006). Some tool extensions allow us to analyze models also for safety (Slåtten et al., 2011) and probabilistic real-time (Han et al., 2013; Han et al., 2014) properties.

BeSpaceD is a constraint solving and non-classical model checking framework (Blech and Schmidt, 2014; Blech and Schmidt, 2013). It emphasizes particularly on dealing with models of cyber-physical systems that usually comprise a large amount of time and space-based aspects. BeSpaceD provides a modeling language and a library to reason on models, using techniques such as state-space exploration,

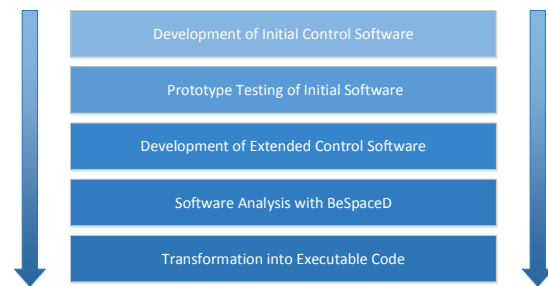

Figure 1: Methodology overview.

abstraction and reduction. It enables the creation of verification goals for SAT and SMT solvers and provides connections to these tools. Thus, these solvers can be used based on much more concrete models than their traditional inputs. On the other hand, BeSpaceD models are more abstract than typical use-case specific (meta-)models that are used in case specific tools. From an expressiveness point of view, SAT and SMT offer the specification elements of propositional logic (+ Presburger arithmetic (Presburger, 1929)). Semantically, using BeSpaceD the notions of time and space are added. Other semantic carrying elements are available: They are treated as predicate parameters and have to be resolved in programs building on the BeSpaceD frameworks or queries to BeSpaceD.

BeSpaceD is written in Scala and compatible with Eclipse/Java. The modeling language is based on abstract datatypes and integrates with the Scala language. It is possible to write one's own programs that construct BeSpaceD models and to write code using BeSpaceD functionality for checking it. In fact, as shown in (Herrmann et al., 2016; Han et al., 2014), an extension of Reactive Blocks is able to transfer its models to BeSpaceD models such that they can be directly analyzed for spatiotemporal properties.

3 METHODOLOGY

The creation of control software for transport systems requires knowledge about central kinematic properties like braking distances or maximum accelerations. Since the systems and their environments are often too complex to gain such data exclusively by simulation, it has to be gathered by testing and observing prototypes. This feature is considered by our methodology (see Fig. 1). It consists of five major steps:

1. In parallel to the development of the physical device, an initial version of the control software is engineered with Reactive Blocks. This first model already contains several functions that will also be

used later in the final version, e.g., the access to sensors and actuators. The functions guaranteeing safety, however, are either not implemented or based on initial data concluded from simulations resp. experience with previous versions.

2. Code is generated from the initial Reactive Blocks model and used in the prototypes which are tested in order to find out relevant kinematic properties.
3. When all relevant properties are observed, the control software is extended. For that, we amend the original Reactive Blocks model by adding building blocks and flows. In this way, existing sub-functionality will be preserved making the development process cheaper.
4. The extended Reactive Blocks model is analyzed by BeSpaceD for compliance with relevant spatiotemporal properties. Depending on the complexity of the verification runs, we may carry out the proofs in two different ways:
 - (a) One extracts a descriptive formula of relevant system functionality from the Reactive Blocks model and transforms it into a format readable by BeSpaceD. Afterwards, BeSpaceD verifies that this specification keeps certain spatiotemporal properties. As shown in (Herrmann et al., 2016), the extraction of the descriptive formulas can be carried out automatically if the Reactive Blocks model was developed based on a certain course of action and a set of dedicated building blocks. Due to its completeness, this kind of analysis is preferred but according to the complexity of the problem might exceed the capabilities of the solvers used by BeSpaceD.
 - (b) One composes the control software model with a simulator that is also created in Reactive Blocks (Han et al., 2014). Thus, several simulation runs can be performed and their logs are translated into input for BeSpaceD that analyzes the data for compliance with the spatiotemporal properties. The log data can be proved very efficiently (e.g., 10,000's of different spatiotemporal coordinates within a split second). But in contrast to the other solution, this one is not exhaustive such that it can only guarantee the preservation of the properties for the simulated cases.
5. When the developed control software fulfills all desired properties, the Reactive Blocks model is transformed into code that is installed in the transport devices and used for further certification steps.

Depending on the kind of system, these steps can also be iterated such that the control software is developed

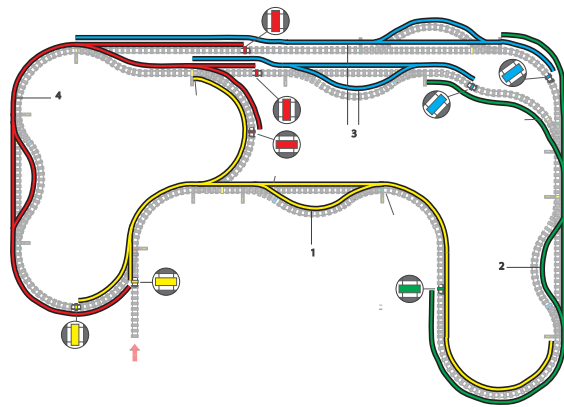

Figure 2: Track control zones.

and analyzed in several cycles. Thanks to the fully automatic nature of the code generation in Reactive Blocks, the results of the engineering cycles can be easily transformed into executable code.

Due to the importance of system safety for life and limb of the later passengers, we do not see our methodology as a replacement for traditional certification but as a supplement. Yet, we expect that the model-based development and spatiotemporal analysis leads to a better quality of the produced software. In consequence, the certification process will have to deal with fewer software errors and therefore is getting smoother.

4 DEMONSTRATOR

As mentioned in the introduction, we use the Lego Mindstorms train-set to exemplify and evaluate our methodology. The overall layout is sketched in Fig. 2. It consists of five different stations that are connected by up to four trains that all operate counterclockwise albeit with possibly different speeds such that a train might catch up with another one. A train set comprises a motor, wheels and a train body (see Fig. 3). Further, we provide each train with a color sensor facing towards the tracks which can be seen on the right side of Fig. 3. It enables the train to count sleepers and to detect special sleepers that are furnished with colored Lego bricks. The coordination of the motor and the color sensor as well as the connection with a wireless communication device is provided by an EV3 controller, the standard control unit of Lego Mindstorms. This unit is transported in one of the cars.

As also shown in Fig. 2, the tracks are partitioned into four *zones* marked by different colors. Each of these zones is controlled by an EV3 unit which coordinates all trains in its zone and prevents colli-

Figure 3: Example lego train.

sions. This resembles the procedure used in the European Rail Traffic Management System (ERTMS), a novel train control system to be used in all European railway networks (ERTMS Project, 2015; UNIFE Project, 2015). Moreover, the zone controller drives the switch points in our system. The beginning of the zones are marked by colored sleepers such that the color sensors of a train can detect when a new zone is entered.

The train controllers are connected with the zone controllers by means of the Message Queuing Telemetry Transport Protocol (MQTT) (MQTT.org, 2015). This is a popular machine-to-machine connectivity protocol often used in the “Internet of Things” domain. Usually, both the routing of connections and the brokerage of users are done by a number of standard MQTT servers. Since tests, however, showed that the use of these servers lead to an unacceptably high transmission delay, we created our own MQTT server that is realized on a Raspberry Pi (Upton and Halfacree, 2014). Figure 4 sketches the communication architecture used. A detailed technical evaluation of the demonstrator can be found in (Hordvik and Øseth, 2015).

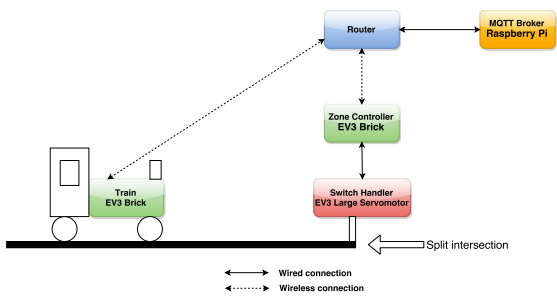

Figure 4: Communication architecture between trains and zone controllers.

4.1 Routing Trains

Fig. 2 highlights that a station consists of two tracks. A stopping track is linked to a platform that allows passengers to enter and leave trains. A second track makes it possible that a train not stopping may pass the station while another one waits in it. Further, at some points we have alternate routes, e.g., for trains going from the station in zone 2 to the one in zone 4. Thus, the trains have to be routed which is done by the zone controllers. For that, the demonstrator is split into 23 different *tracks* that are each bordered by two switch points. The beginning of each track is marked by an unambiguously colored sleeper such that a train can always follow up on which track it is currently located. As shown in the message-sequence-chart in Fig. 5, a train provides the responsible zone controller with its destination. Based on that, the zone controller selects the tracks, the train has to pass in its zone, and sets the switch points accordingly. The routing algorithm is based on work described in (Overskeid, 2015).

The switching of zones by a train is realized by a sequence of colored sleepers as depicted in Fig. 6. First, the train passes a green sleeper indicating that not a new track is entered but that a zone shift is coming up. Since a zone switch affords the time-consuming establishment of a new connection between the train and zone controller, we use overlapping segments in which the train is controlled by both involved zone controllers. The beginning of the overlapped segment is marked by a sleeper in the color of the new zone. When passing it, the train controller starts building up a MQTT connection with the new zone controller. The end of the overlapping segment is identified by a colored sleeper that signals the beginning of a new track in the newly entered zone. It may only be passed if the connection with the controller of the new zone is established and thereafter, the link with the controller of the old zone is released.

4.2 Collision Avoidance

As mentioned above, the zone controllers are responsible for preventing collisions of trains in their zone. For that, they permanently need information about the exact positions and speeds of the trains. Since color sensors are the only sensing equipment used in our demonstrator and Lego trains have the nice feature that sleepers are always in the same distance from each other irrespectively of the track shape, we use the sleepers as means to define exact train positions. In particular, each train controller maintains a so-called *sleeper counter* that totals how many regu-

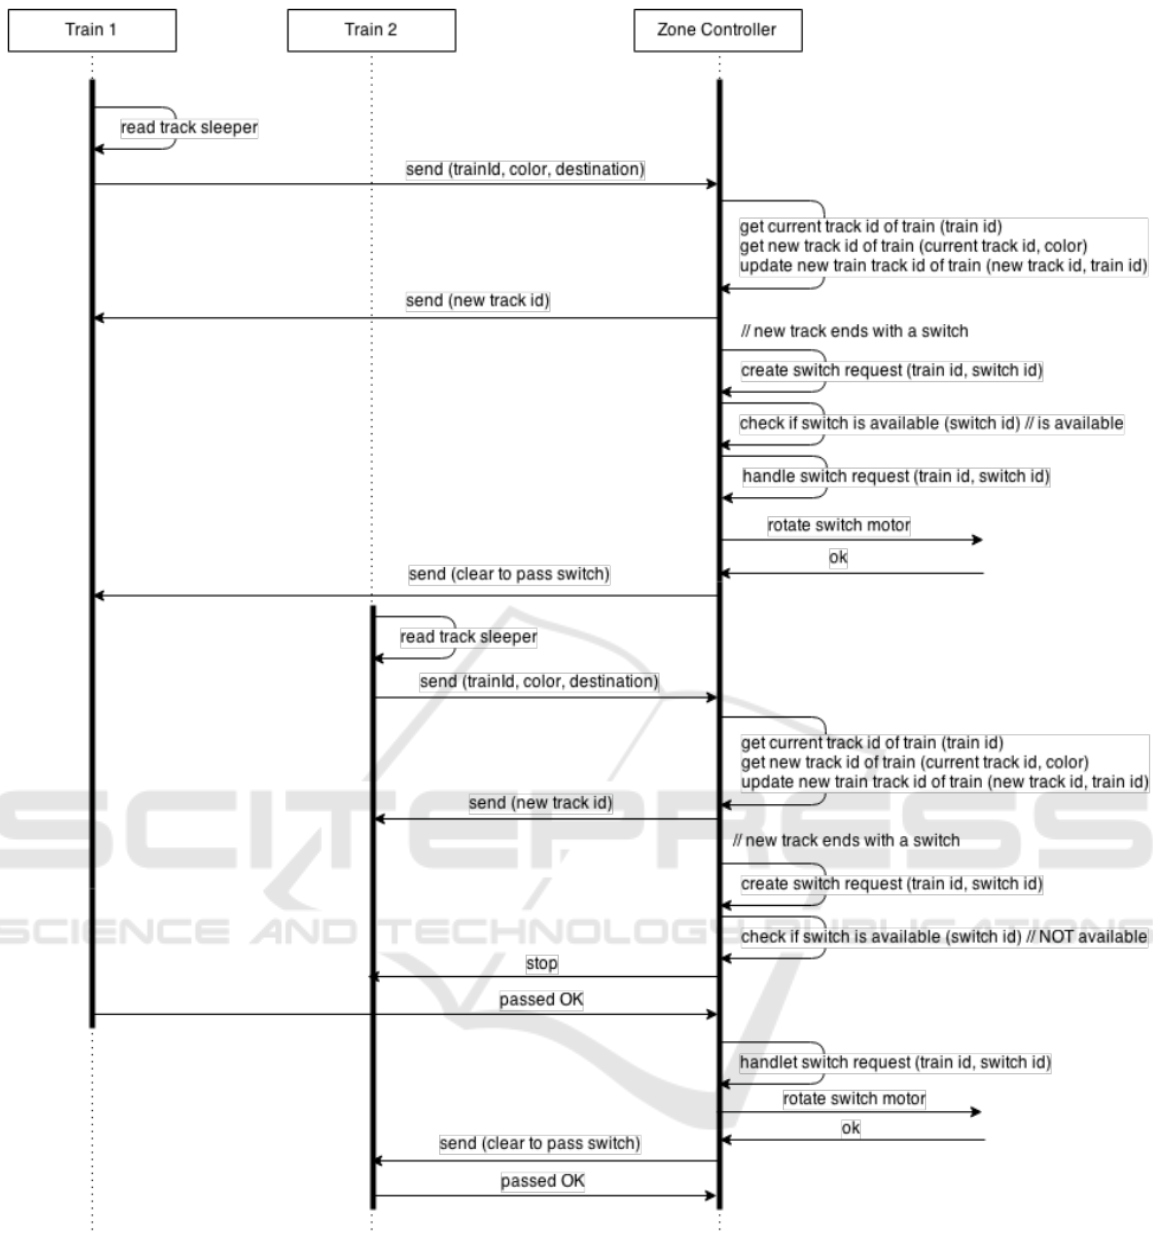

Figure 5: Two trains interacting with a zone controller.

lar, i.e., non-colored, sleepers of the track on which it currently moves, it already passed. Further, by using time-stamps and knowing the distance between the sleepers, a train calculates its current speed. Whenever a regular sleeper is passed, the train sends the value of its sleeper counter and speed value to the responsible zone controller (resp. zone controllers if the train is on an overlapping track), see Fig. 5.

From these data and its knowledge about the current track of the train, the zone controller establishes which sleeper the train just entered. It sets this sleeper

and, with help of the information about the train's length, all other sleepers that are covered by the train into state *occupied*. Due to its knowledge about the system layout, the zone controller may also consider the sleepers of the previous track if the train just passes a track border.

In addition, the sleepers vacated by the train since the last notification was received, are set to *free*. The zone controller checks if the train is on a collision course with another one. Based on the current speed and position of the train, it calculates the dis-

Figure 6: Sleepers indicating zone switches.

tance needed for the train to come to a complete stop. This distance is converted into the number n of sleepers that are passed before the train stands after cutting power. Moreover, taking the communication delay between the zone and train controllers into consideration, we add a safety buffer b of sleepers¹ to n . If at least one of the $n + b$ buffers ahead of the train is occupied, the zone controller sends immediately a stop message to the train that initiates an emergency stop. Of course, this holds also for sleepers in the subsequent track when the train reaches the end of the previous one. If all the next $n + b$ buffers are not occupied, an all-clear signal is sent, and the train may continue with its current speed. Since the zone controller may have been broken, the train it also stopped when no signal at all arrives within a certain period of time.

The logic also includes the option of using an extra buffer such that the zone controller will check the state of sleepers that are even further in front of the train. Are any of these sleepers occupied, the controller commands the train to slow down, instead of coming to a complete stop. If the blocking train in front continues to stand still, the emergency break is initiated a little closer to it due to the reduced speed, which leads to a smoother operation.

5 ENGINEERING THE CONTROLLERS OF THE DEMONSTRATOR

The development of the control software for our demonstrator followed tightly the methodology presented in Sect. 3.

¹It is important to note that, the bigger the safety buffer b is, the more states of sleepers need to be checked, which means more processing time and again a bigger latency with regards to when the train receives a response. By testing the braking distances of the trains with various safety buffer values, we found out that $b = 10$ gives the best results.

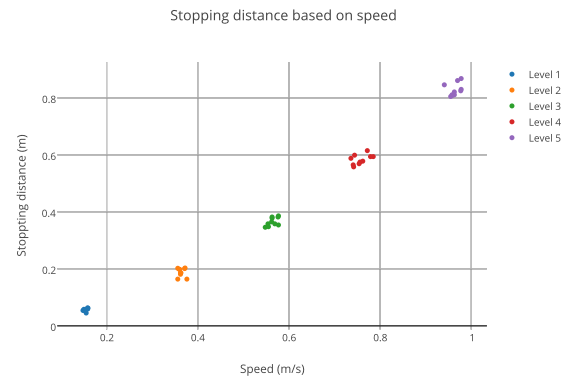

Figure 7: Breaking distance for different speed levels.

5.1 Methodology Step 1

The creation of an initial software version profited strongly from work by (Overskeid, 2015) who developed building blocks that facilitated the handling of the access to the EV3 train and zone controllers from the Reactive Blocks model. These blocks could be simply combined to achieve a first user-managed control system.

5.2 Methodology Step 2

We used the initial control software to find out the relevant kinematic properties of the trains. In particular, we analyzed the stopping distances for five of the seven speed levels² offered for Lego Mindstorms trains. Fig. 7 depicts that, as expected, the braking distances are parabolic albeit with a relatively small gradient. Using these results and the fact that two sleepers are in a distance of 32.5 cm, we could determine the numbers n of sleepers to be considered for each speed level in the collision avoidance scheme discussed in Sect. 4.2.

Moreover, in this phase we examined the color sensors more closely to get good readings. With respect to speed calculation, we checked three alternatives, i.e., computing the speed after passing 16.25 cm, 32.5 cm resp. 65 cm. The tests revealed that the longest distance which corresponds to computing the speed only after every second sleeper, rendered by far the best measurements. Further, we detected quality issues for sensing different colors. We found out that we get better results if the color sensor is in a distance of 12 mm above the track than the 6 mm tried originally. We also discovered that the likelihood to detect the correct color is significantly improved when

²The track layout contains many turns such that the two highest speed levels would lead to immediate derailments. Therefore, we did not consider them further.

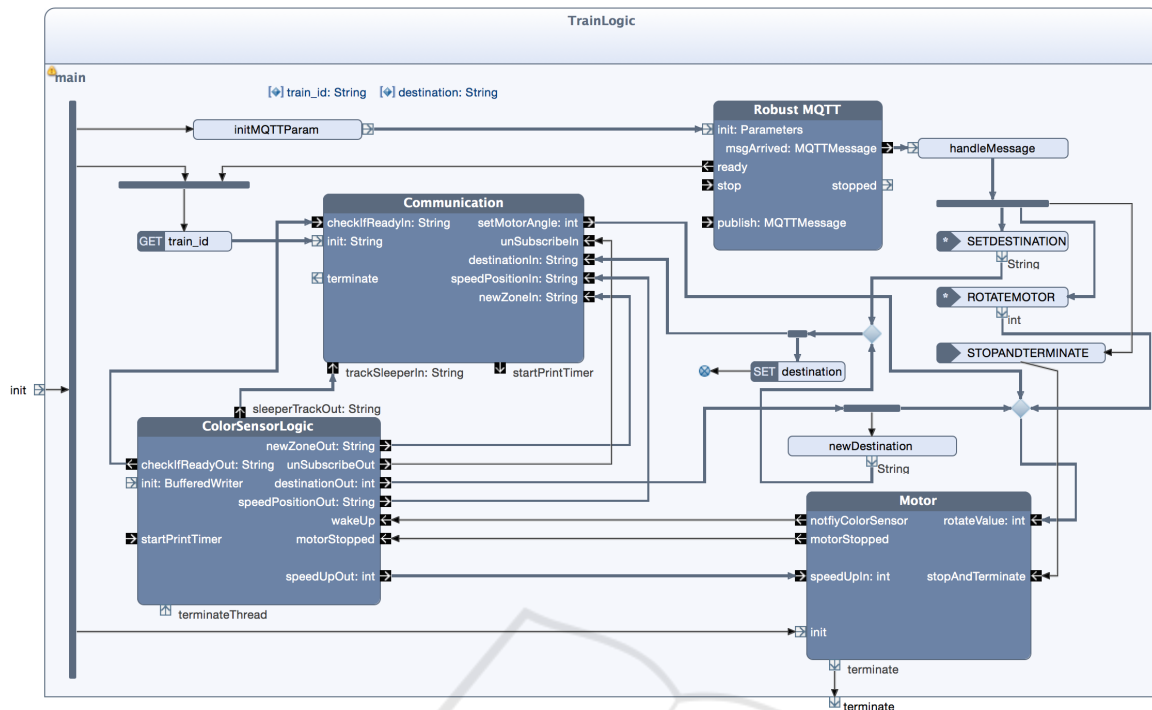

Figure 8: Building block for the train control logic.

the thread handling color changes pauses between two checks for exactly 14 ms. When it runs without pausing, often white color is falsely read. In addition, we found out that, in general, blue and green render better results than red and yellow. We took these experiments into consideration when deciding which colors to be used at which points in the layout.

5.3 Methodology Step 3

After getting sufficient knowledge about the kinematic behavior of the demonstrator as well as the correct treatment of the color sensors, we continued with the creation of the final control logic using Reactive Blocks. As an example, Fig. 8 depicts the UML activity of the building block `TrainLogic` specifying the control logic of the train controllers. It contains four inner building blocks. Block `Robust MQTT` was taken from a Reactive Blocks library. It specifies the logic to handle connections with the MQTT server. Building block `ControlSensorLogic` models the access to the color sensor and the interpretation of the metered colors as described in Sect. 4. Block `Motor` is based on work in (Overskeid, 2015) and specifies the control of the train engine. Finally, building block `Communication` defines the cooperation with the responsible zone controller(s) via MQTT.

The semantics of UML activities resemble Petri Nets such that we can interpret a control or data flow

as tokens running via the edges to the various vertices of the activity. The block `TrainLogic` is started by a flow through the incoming parameter node³ `init` that is forked into three flows. One flow leaving the fork leads to the operation `initMQTTParam` that is a carrier of a Java method creating an object of type `Parameters`. This object carries the data needed to start an MQTT connection. It is forwarded towards pin `init` of block `Robust MQTT`. The other two flows leaving the fork initiate the blocks `Communication` and `Motor`. The block `ControlSensorLogic` does not need to be initialized. It gets active when the motor starts operating.

The other flows of the activity are only sketched. There are several flows from `ControlSensorLogic` to `Communication` modeling the notification of the zone controller about the various findings of the color sensor. The control of the train speed by the zone controller is specified as a flow from pin `setMotorAngle` of building block `Communication` that defines the desired speed level as an integer value. This flow is forwarded to pin `rotateValue` of block `Motor` after which the engine speed is adjusted. Two flows from `Motor` to `ControlSensorLogic` realize that the color sensor is only operative if the motor turns. Finally, the activity contains three event receptions used to control the

³The term *parameter node* refers to pins at the edge of a UML activity.

train directly from the central console. They can be used to set destinations for the train, to manage the motor directly from the console, and to terminate the train controller. In the latter case, an event of type *STOPANDTERMINATE* leads to block *Motor* in order to stop the train and to switch off the color sensor before the building block *TrainLogic* is terminated by a flow through parameter node *terminate*.

The model checker and animator of Reactive Blocks (Kraemer et al., 2009) proved helpful to check our controller models for functional correctness. The built-in model checker verified general functional properties, e.g., that all flows in a block are consistent to the interface descriptions of both, the ESM of this block and those of the inner blocks. The animation feature which allows to highlight flows of a block that can be executed in a certain state, was used to analyze our models for problem-specific properties. For instance, by inspecting all states of building block *TrainLogic* (see Fig. 8) we found out that a train controller does only unsubscribe the MQTT connection with a zone controller if it currently is connected with two of them. Thus, except for the system start, a train controller is always connected with at least one zone controller as long as no MQTT connection breaks.

5.4 Methodology Step 4 (b)

```

Figure 9: Train data in BeSpaceD.

As stated above, the development of the Reactive Blocks model is in parts based on work from (Overskeid, 2015) which did not use the special building blocks needed to enable an automatic extraction of the control logic as described in step 4a of the methodology. Therefore, we decided to use alternative 4b instead, i.e., we applied BeSpaceD to check

logs of runs observed by executing the control software. Since Lego trains are usually not damaged by crashes, we could not only get runs from pure simulation but also from running the real trains on the tracks. In Sect. 4.2, we explained that sleepers form the basis for describing the locations of trains as well as breaking distances. Therefore, it seemed natural to use them also in the BeSpaceD proofs. The simulation resp. operation of the train and zone controllers lead to formulas as sketched in Fig. 9. A formula comprises a long list of conjunctions marked by a *BIGAND* statement. Each conjuncted element features an *IMPLIES* statement describing that a time point implies that a train occupies a certain number of sleepers on the track.

We used BeSpaceD to check runs of various scenarios mostly to guarantee freedom of collisions. Here, the solvers were used to verify that no sleeper was occupied by more than one train⁴ at any time. But we could also validate that the results observed in step 2 of the methodology are consistent with the observed runs. For instance, the higher complexity of the final control software did not impact the braking distances compared with the observed ones (see Fig. 7). The BeSpaceD proofs did not reveal any performance problems. The longest run comprised 1973 time points that correspond to more than 32 minutes of operation and afforded the check of 10,000's of sleepers. They were checked within 0.3 s each on a standard 2.8 Ghz Intel Core i5 running MacOS.

5.5 Methodology Step 5

Finally, we got the implementation by automatic generation of Java code from the Reactive Blocks models that was exported to the EV3 controllers as executable .jar files. This procedure could be performed for all controllers of our system within a few minutes.

6 EXPERIENCE FROM BUILDING THE DEMONSTRATOR

Together with general library blocks like timers or buffers and, in particular, the blocks to handle MQTT (MQTT.org, 2015), around 55% of the model had not to be created from scratch but could be reused.

⁴The inaccuracy of using sleepers for measurement was compensated by overapproximating the length of the trains, i.e., we declared a crash even when only one sleeper lay between those occupied by two trains.

Albeit we have used Reactive Blocks to build transport system controllers only for a relatively short time, that is not too far from the reuse rate of 70% that is usually achieved when creating models in already well-supported application domains (Kraemer and Herrmann, 2009).

We were also pleased that the input formulas for BeSpaceD could be easily generated and proved within very short time frames. We learned, however, that the necessity to use certain blocks in order to create descriptive formulas of the control software as used in alternative 4a of the methodology, might lead to practical problems. The engineer likes to be as free as possible when creating or selecting models in order to be able to address particular design problems flexibly. Thus, the rigid structure of the blocks needed to facilitate the creation of the BeSpaceD formulas (Herrmann et al., 2016) may be seen as cumbersome. We need to spend more work in solving this conflict between easy development and analysis.

7 RELATED WORK

In the past, verification and analysis tools have been typically studied with respect to the underlying verification and analysis techniques rather than emphasizing the domain. PHAVer (Frehse, 2005) is a tool that allows the analysis of spatial properties in hybrid-systems. Another application of formal verification techniques to train systems is described in (Platzer and Quesel, 2009). Here, deduction-based verification techniques from the KeYmaera system (Platzer and Quesel, 2008) are applied. An application of the SPIN model checker for the verification of control software aspects of a railway system is described in (Cimatti et al., 1998). A variety of other generic tools, recent work and approaches, e.g., (Caires and Torres Vieira, 2012; Cimatti et al., 2015; Tiwari, 2015) for model checking spatial properties of cyber physical systems exist. The combination of Reactive Blocks with BeSpaceD has been studied, e.g., in (Han et al., 2015; Herrmann et al., 2016). Here, the emphasize is on robots and either measured or simulated spatiotemporal values. Unlike in this paper, the combination of simulation and measured values was not considered.

The European Rail Traffic Management System (ERTMS) is a major industrial project undertaken by the Association of the European Rail Industry members. Its main focus is on creating a seamless integrated railway system in Europe to increase European railways competitiveness, capacity, reliability rates and safety (ERTMS Project, 2015; UNIFE Project, 2015). A relevant focus is the automatic

train protection system named European Train Control System (ETCS), and the Global System for Mobile Communications – Railway (GSM-R). GSM-R is based on the GSM standard and provides voice and data communication between the track controllers and the train. It uses frequencies specifically reserved for railroad applications. A variety of other large scale European funded projects exists in the domain of safety-critical cyber-physical system. For example, the ARTEMIS Chess (CHESS-Consortium, 2010) project includes a focus on the rail domain. Among other results, it produced a modeling language.

Our work uses a similar lego infrastructure as (Overskeid, 2015) where new means for public transport have been studied based on Lego Mindstorms and Reactive Blocks. In contrast to Overskeid’s work, however, ours is more centered on software quality, in particular, with respect to making systems safe. For that, the separation of the control functionality between train and zone software is performed in a novel way that disburdens the performance of the EV3 controllers better when a larger number of trains has to be coordinated. Further, the use of BeSpaceD enables us to verify relevant spatiotemporal properties formally. Finally, following the methodology presented in Sect. 3 facilitates carrying out a well-regulated software engineering process.

8 CONCLUSION

We described our methodology that is able to check safety properties on measured and simulated data collected from a transportation system. A major effort of the paper is the realization of a demonstrator and the application of the methodology to the demonstrator, as well as its evaluation.

Currently, we continue our work by using the introduced methodology for two other projects. The one is an extension of the train layout such that traffic in both directions will be possible. Further, the zone controllers shall be replaced by direct collaborations of the train controllers that work together in order to achieve the spatiotemporal properties. The other approach will use the methodology for a set of robots controlled by Raspberry Pies (Upton and Halfacree, 2014) that, in addition to not colliding, shall cooperate in order to, e.g., transport certain pieces together without letting them fall down. Moreover, we discuss with Statens Vegvesen, the Norwegian Public Roads Administration, and Jernbaneverket, the Norwegian Government’s Agency for Railway Services,

how to introduce our research into the development and licensing process of real transport systems.

Other future work centers on investigating the use of the introduced platform and methodology in the context of collaborative engineering (Blech et al., 2014). In particular, we aim at providing the BeSpaceD-based safety analysis as a cloud based service. We are also working on using analysis results to provide adequate views to operators and other stakeholders using devices providing different form factors. A first practical usage is the remote monitoring of the Lego Mindstorms demonstrator. For that, several methods to visualize the operational state of the trains are under development.
