Abstract: When designing electronic circuits, available synthesis flows either focus on accelerating the synthesized circuit or correctness. In the quest for ever-faster hardware designs, the correctness of these designs is often neglected. Thus, designers need to trade-off between correctness and performance. The question is how large the trade-off is? This work presents a systematic comparison of two representative synthesis flows, the LegUp HLS framework as a representative for flows focusing on hardware acceleration, and a flow based on the proof assistant Coq focusing on correctness. For evaluation purposes, a 32-bit MIPS processor synthesized using the two flows, and the final HDL implementations are compared regarding their performance. Our evaluation allows a quantitative analysis of the trade-off, showing that correctness-oriented synthesis flows are competitive concerning performance.

1 INTRODUCTION

Electronic circuits have become more and more complex over time. The goal of synthesis flows is either to synthesize accelerated circuits which have a high performance or correct ones which guarantee correctness properties. As synthesis flows with an emphasis on acceleration often do not provide the ability to formulate correctness proofs, these design flows are a severe issue when applied in safety-critical systems such as cars, airplanes, or medical devices. This comparison leads to the question of whether both flows can be combined to get the best of both worlds.

To address this question, we first take a look at synthesis flows with an emphasis on acceleration. To tackle the synthesis of faster hardware designs, synthesis flows like Bambu (Pilato and Ferrandi, 2013), DWARV (Nane et al., 2012), or LegUp (Canis et al., 2013; Canis et al., 2016) evolved (in the following called *acceleration-oriented synthesis flows*). These flows start with a model written in a Domain-specific language (DSL) to describe hardware designs that are embedded into the C programming language. After the model is implemented, it is synthesized into a low-level implementation in a hardware description language (HDL) at the Register-Transfer-Level (RTL), e.g., Verilog. During the automatic synthesis process,

different optimizations like loop or functional pipelining (Canis et al., 2013; Hwang et al., 1991) are performed to accelerate the final implementation.

One problem with these synthesis flows is the missing definition of a synthesis scheme (Eisenbiegler and Kumar, 1995; Baaij and Kuper, 2013) and the resulting lack of property verification. In general, it is unclear (1) how the implementation is generated from the model in detail; (2) whether the semantics of the model are correctly represented by the semantics of the implementation; and (3) how to track and verify properties stated at the specification level in the implementation.

In contrast, synthesis flows with an emphasis on verification like Kami (Choi et al., 2017) or the one based on Coq (Bertot and Castéran, 2004) and C λ aSH (Baaij et al., 2010) as introduced in (Bornebusch et al., 2020) start with a specification in a formal language that allows the verification of functional properties about the hardware design (in the following called *correctness-oriented synthesis flows*). After the specified behavior was verified, an RTL implementation is synthesized automatically. This way, these flows guarantee a correct transformation of the semantics of the specification to the final implementation and, hence, ensure the verified properties hold on all levels.

However, while these approaches can guarantee correctness, it remains unclear how the performance of the resulting designs compares to the performance of designs obtained by the acceleration-oriented synthesis flows reviewed above. In fact, it is intuitive to assume that a focus on verification may harm this performance. But unfortunately, this possible trade-off has not been addressed in detail yet. While anecdotal evidence suggests correctness-oriented flows can be competitive with respect to performance, we present a systematic analysis by comparing the design of a non-trivial circuit with two representative flows from each camp.

The missing trade-off leaves designers with the question of whether they should focus on correctness (motivating the utilization of a correctness-oriented synthesis flow) or on performance (motivating the utilization of an acceleration-oriented synthesis flow).

This paper addresses this question. To this end, we investigate both design flow paradigms – using the LegUp high-level synthesis (HLS) framework (Canis et al., 2013; Canis et al., 2016) and the synthesis flow from (Bornebusch et al., 2020) as a representative for acceleration-oriented and correctness-oriented synthesis, respectively. We chose those flows as they represent the most efficient (cf. (Nane et al., 2016)) and most recent flows available thus far, implementing the respective concepts. The foundation of the investigation is a 32-bit MIPS processor (Hara et al., 2009), which is synthesizable by LegUp. The functional behavior of this processor is specified, verified, and synthesized using the correctness-oriented flow, described above.

Our quantitative analysis of the processor implementations gives a first impression to gauge the trade-off between performance and correctness. Even though there will be cases that justify the application of the acceleration-oriented flows, our analysis shows the potential of further research of applying correctness-oriented flows in an industrial setting, even in cases where performance is a critical issue. Moreover, it is easier to increase the performance of circuits synthesized by correctness-oriented flows than to make hardware designs following acceleration-oriented flows correct.

We do not discuss whether an acceleration-oriented model or a correctness-oriented specification is more user-friendly as this question is too subjective to answer.

This work is structured as follows: first, we motivate our work by describing and discussing the LegUp synthesis flow and the considered problem we address in this work. Section 3 describes the correctness-oriented synthesis flow in detail and how it addresses

the considered problem. Section 4 describes our specification of the processor and how properties are verified. Section 5 evaluates and discusses the RTL implementations. Finally, Section 6 summarizes this work.

2 MOTIVATION

This section analyzes the LegUp HLS framework synthesis flow (Canis et al., 2013) as a representative of a contemporary, state-of-the-art acceleration-oriented synthesis flow. On average, LegUp synthesizes the fastest hardware designs, which is the reason for picking it as a representative (Nane et al., 2016). This flow analysis shows the missing ability to verify correctness properties of models implemented for these flows.

An available model of a 32-bit MIPS processor is used as a running example to analyze the synthesis flow implemented by the LegUp HLS framework (Hara et al., 2009; ?). The MIPS architecture describes an instruction set architecture (ISA) for a reduced instruction set computer (RISC) (MIPS, 2016).

2.1 The LegUp Synthesis Flow

The foundation of the LegUp framework is the LLVM (Low Level Virtual Machine) compiler infrastructure (Lattner and Adve, 2004). LLVM is a modular compiler infrastructure for optimized code generation. A model is transformed into LLVMs internal intermediate representation, which is a machine-independent assembly language using the Clang compiler front-end and later optimized by a series of built-in compiler optimizations. LegUp extends the LLVM backend by generating Verilog code instead of Machine code (Canis et al., 2013). In order to accelerate hardware designs, different additional optimizations are performed during the optimization process by LegUp, e.g., loop or functional pipelining (Canis et al., 2013; ?).

These optimizations aim to identify behavior that can be accelerated. Whether an optimization can be performed and, therefore, result in an implementation that satisfies the required performance properties depends on the used model.

For modeling designs, LegUp defines a Domain-specific language embedded into the C programming language. Two modes are provided to synthesize a model. The first mode is the generation of a hybrid processor/accelerator architecture. The described behavior of a model is compiled and executed on a dedicated processor that profiles its ex-

Figure 1: Sketched LegUp synthesis flow for pure hardware designs. A model in a hardware DSL is synthesized into an accelerated low-level implementation in Verilog automatically.

```

ins = imem[IADDR (pc)];
op = ins >> 26;
switch (op) {
  case R:
    funct = ins & 0x3f;
    shamt = (ins >> 6) & 0x1f;
    rd = (ins >> 11) & 0x1f;
    rt = (ins >> 16) & 0x1f;
    rs = (ins >> 21) & 0x1f;
    switch (funct) {
      case ADDU:
        reg[rd] = reg[rs] + reg[rt];
        break;
      case SLL:
        reg[rd] = reg[rt] << shamt;
        break;
    }
  [...]
  address = ins & 0xffff;
  rt = (ins >> 16) & 0x1f;
  rs = (ins >> 21) & 0x1f;
  case ADDIU:
    reg[rt] = reg[rs] + address;
    break;
  [...]
  case J:
    tgtadr = ins & 0x3ffffff;
    pc = tgtadr << 2;
    break;
}

```

Listing 1: Extract from the 32-bit MIPS processor model that contains the ADDU, SLL, ADDIU, and J instruction (Hara et al., 2009). The model is implemented as a state machine that iterates over the instructions. The current instruction is separated into its parts using logical *shift* and logical *and* operations.

ecution. After profiling, segments of the model are selected that are accelerated by hardware implementations. The final part is re-compiling the model into a hybrid hardware/software system (Hardware/Software Codesign (Ha and Teich, 2017)).

The second mode is the automatic synthesis of a model in a pure and accelerated RTL implementation, sketched in Figure 1. After the implementation is generated, it can be synthesized on an FPGA using commercial synthesis tools. In contrast to the first mode, constructs like dynamic memory management, recursion, and floating-point arithmetic are not supported (Canis et al., 2013).

In this paper, we focus on the second mode. Since the running example used in this work describes a 32-bit MIPS processor, the model is synthesized to pure hardware.

Example 1. *In order to analyze the LegUp synthesis flow regarding the verification of properties, we con-*

sider a 32-bit MIPS processor implementation. This implementation is already the subject of current research (Hara et al., 2009; Nane et al., 2016) and is sketched in Listing 1. The model implements a subset of the 32-bit MIPS standard instruction set, roughly 40 instructions. It also provides an implementation of a program that is a set of bit-vectors and follows the bit order for instructions stated by the 32-bit MIPS instruction specification (MIPS, 2016).

According to the program counter, each instruction is processed in one iteration and is read from the instruction array. It is separated into its parts, e.g., the operation code, function code, or operands. After separation, the instruction is processed according to its operation code or function code. The program counter is changed after instruction execution so that the next instruction is read from the instruction array. The model also contains a register file storing 32 entries and a data memory storing 64 entries. The execution of the iterations is stopped by a dedicated instruction (syscall 10), which means exit and is part of the program.

2.2 Considered Problem

LegUp implements a new LLVM backend to synthesize hardware designs to Verilog implementations (Canis et al., 2013). LegUp’s input language defines a sequential execution scheme, but hardware designs define a parallel one. To formally describe the transformation of a sequential scheme into a parallel one, *synthesis schemes* (Eisenbiegler and Kumar, 1995; Baaij and Kuper, 2013) can be used. According to the LegUp authors (Canis et al., 2013), the transformation from LLVM’s internal representation language to Verilog does not follow such a synthesis scheme. The same goes for synthesis flows implemented by Bambu (Pilato and Ferrandi, 2013) and DWARV (Nane et al., 2012). As a result, it is unclear how properties formulated at the model level relate to the implementation and how one could verify them. Moreover, it is unclear how to formulate properties in the hardware DSL because of its embedding into C. While there are tools to state and verify properties of C programs, such as Frama-C (Cuoq et al., 2012) or Astrée (Cousot et al., 2005), these tools assume a compiler behaving according to the semantics defined by the C standard (CStandard, 1999). These assumptions are not the case for hardware designs as just described.

The missing ability to verify properties of models using the LegUp synthesis flow leads to the following questions. First, can we synthesize the 32-bit MIPS processor with a different synthesis flow that al-

lows us to prove its correctness? Second, what would be the performance of the final implementation compared to the implementation synthesized by LegUp?

3 CORRECTNESS-ORIENTED SYNTHESIS FLOWS

In contrast to the acceleration-oriented synthesis flows just introduced, there are other synthesis flows like the correctness-oriented flows implemented by Kami (Choi et al., 2017) or (Bornebusch et al., 2020). In this section, we discuss and evaluate both flows to address the considered problem.

The idea of formally describing hardware using higher-order logic to prove correctness properties (formal synthesis) is not new (Kumar et al., 1996; Gordon et al., 2006; Hanna et al., 1989). Higher-order logic was used to avoid the combinatorial explosion of test vectors to ensure correctness and use symbolic reasoning instead. One of the first frameworks using this methodology were LAMBDA/DIALOG (Finn et al., 1989) and VERITAS (Hanna et al., 1989). Elaborating this methodology further description languages using higher-order logic, such as Hardware ML (HML) (O’Leary et al., 1993) and Bluespec (Arvind, 2003; ?), were invented. The invention of Bluespec resulted in a hardware description language embedded into the proof assistant Coq to provide an automatic synthesis process that extracts a low-level implementation from a verified specification (Choi et al., 2017).

Kami and the Coq/ClaSH flow rely on the proof assistant Coq (Bertot and Castéran, 2004; Chlipala, 2013) to specify and verify hardware designs and synthesize them afterwards in an implementation automatically. Coq specifies a functional behavior using the *Calculus of Inductive Constructions* (CiC). This formal language combines higher-order logic and a richly-typed functional programming language, called Gallina. As higher-order logic is too expressive for automatic reasoning, a separated tactic language (Delahaye, 2000), called L_{tac} , is provided to let the engineer guide Coq’s reasoning engine through the proof. Properties about the specified behavior are proven in this tactic language. As the engineer guides the reasoning process, proof assistants are also called interactive theorem provers. The synthesis flow of both Kami and the one proposed in (Bornebusch et al., 2020) is sketched in Figure 2.

To our knowledge, Kami was the first project that proposes a formal processor specification extracted to a low-level implementation. Kami embeds a Domain-specific language (hardware DSL) into Gallina to de-

Figure 2: The correctness-oriented synthesis flows start with a specification using the proof assistant Coq. From the specification, a model in Bluespec (Kami) or ClaSH (Bornebusch et al., 2020) is extracted. The model is finally synthesized to an RTL implementation, e.g., in VHDL or Verilog.

scribe hardware designs functional (Choi et al., 2017). This language is based on the Bluespec hardware description language (Arvind, 2003). An executable Bluespec Verilog model is extracted from the specification, which is the input language for the Bluespec compiler. This compiler synthesizes a model to a hardware implementation in Verilog (Arvind, 2003).

The hardware design synthesis flow introduced in (Bornebusch et al., 2020) adds the hardware DSL ClaSH (Baaij et al., 2010) to Coq’s extraction backend. It uses Coq’s specification language Gallina to describe the functional behavior of hardware designs. After the verification process, an executable ClaSH model is extracted from the specification. ClaSH is a functional hardware description language that borrows both its syntax and semantics from Haskell. The ClaSH model is finally compiled into a low-level implementation at the Register-Transfer Level (RTL). The supported HDLs are SystemVerilog, Verilog, and VHDL.

In contrast to the acceleration-oriented synthesis flows such as implemented by LegUp, both of these flows formulate a synthesis scheme describing how the semantics of the specification propagates to the final implementation. This synthesis scheme ensures that the proven properties at the specification level also hold for the implementation.

Both flows seem capable of addressing the problem discussed in Section 2.2. They allow the specification and verification of the 32-bit MIPS processor and subsequently synthesize the design on an FPGA. For example, Kami has been used to implement a RISC-V multi-core processor as a case study (Choi et al., 2017). However, the flow (Bornebusch et al., 2020), which we call Coq/ClaSH in the rest of the paper, is more light-weight and flexible, as ClaSH allows the synthesis of arbitrary combinational and synchronous sequential hardware designs (Baaij et al.,

2010; Bornebusch et al., 2020). Because of its flexibility, we chose this one as a representative of correctness-oriented hardware synthesis flows.

However, the question remains whether such correctness-oriented synthesis flows will result in less efficient designs concerning the performance of the synthesized circuit? After all, correctness-oriented flows emphasized property verification and not so much on the acceleration of implementations. For this reason, one would not be surprised if the implementation synthesized by the Coq/ClaSH flow would be slower than the one synthesized by LegUp. Even then, the question would remain by *how much* the design would be slower.

4 SPECIFICATION AND VERIFICATION OF THE MIPS PROCESSOR

In this section, we describe the specification of the 32-bit MIPS processor in Gallina, using the Coq/ClaSH hardware design synthesis flow, and how properties about it are stated and verified. By this, we provide an analysis of the correctness-oriented design flow and a benchmark that, afterward, is used to compare to the acceleration-oriented design flow. The foundation regarding the implemented instructions, register file, and memory is the 32-bit MIPS processor, described in Section 2.1.

4.1 Specification of Sequential Hardware Designs

To represent sequential circuits functionally in the Coq/ClaSH synthesis flow, Mealy or Moore machines are used (Bornebusch et al., 2020). These machines abstract the clock by defining state transitions, which allow a time-controlled execution. The advantage of such a description is that we can prove properties such as liveness (Broy, 2014) about the hardware design. The type of the Mealy machine specified in Gallina is shown in Listing 2. In this case, a Mealy machine is used, as we need access to the program counter in the current state for calculating the output, as we see later.

```

Fixpoint mealy {S I O:Type}
  (f: S -> I -> (S*O))
  (s: S)
  (l: list(I))
  : list(O)
    
```

Listing 2: Function type of the *Mealy* machine specified in Gallina (Bornebusch et al., 2020). The machine takes a function as its first argument. This function maps a state (S) and an input (I) to a tuple of a new state and an output (S*O). An initial state and a list of inputs is also required by the function type. The result is a list of outputs. The types S, I, and O are inferred at compile time.

The recursive specification of the Mealy machine calls the function *f* with the current state and input, and returns a new state and an output, until every input is processed.

In our case, the program counter, the register file, and the memory define the state (S). The input (I) is ignored by our specification of function *f*, as the benchmark (the program mentioned in Section 2.1) is a fixed set of instructions. Since an output (O) is required, the result of an instruction is returned. Listing 3 shows the instantiated function type of function *f* required by the Mealy machine definition. The *registerFileType* and the *memoryType* are fixed-sized vectors of the length 32 and 64, respectively.

```

Definition mips
  (data : registerFileType*memoryType*
    Unsigned32.int)
  (dummy : bool)
  : (registerFileType*memoryType*
    Unsigned32.int)*Unsigned32.int
    
```

Listing 3: Function type of the *mips* function specified in Gallina.

The first argument is called *data*. It is a tuple of the *RegisterFileType*, the *memoryType* and the *Unsigned32.int* type. The first two types are vectors of a fixed size that represent the arrays of the LegUp model. The third type represents the program counter. The second argument to the *mips* function is of the type boolean. The Coq/ClaSH synthesis flow used in this work extracts a ClaSH model from a specification. Since the MIPS processor model defines a constant set of executed instructions, there is no actual input, so we call that argument *dummy*. The return type is a tuple of the same tuple as the first argument and a 32-bit unsigned value (*Unsigned32.int*). This value defines the output of the Mealy machine, e.g., the result of an instruction.

After an instruction was executed, the changed register file, the changed memory, and the new program counter are returned (the new state). How the register file or memory is changed depends on the executed instruction.

4.2 Construction of Instructions

The instructions, together with their operands, are encoded as 32-bit unsigned integer values. These instructions are specified in three different formats. In addition to the operation code (op), which they all have in common, they differ in interpreting their bits. The operation code always consists of the highest six bits. The first format is the R-Format that specifies three registers, one shift amount, and one function code and has the following layout:

$$\underbrace{op(6) \ rs(5) \ rt(5) \ rd(5) \ shamt(5) \ funct(6)}_{31 \dots 0 \ bits}$$

The three registers state the first register operand (rs - 5 bits), the second register operand (rt - 5 bits), and the register destination (rd - 5 bits). The shift amount (shamt) also has 5 bits, while the function code (funct) has 6 bits. The operation code in the R-Format is always zero. The second format is the I-Format. In addition to the operation code, this format specifies two registers and one immediate value and has the following layout:

$$\underbrace{op(6) \ rs(5) \ rt(5) \ immediate(16)}_{31 \dots 0 \ bits}$$

The operation code and the two registers have the same bit sizes as in the R-Format. The immediate value is 16 bit in size. The third format is the J-Format and states one address value, which results in the following format:

$$\underbrace{op(6) \ address(26)}_{31 \dots 0 \ bits}$$

The address value is 26 bits in size.

These formats enable a unique interpretation of the instruction bits. Our specification of the 32-bit MIPS processor, sketched in Listing 1, is shown in Listing 4.

To separate an instruction into its parts, we implemented a couple of functions. We illustrate the implementations of these functions by reference to the *ADDU* instruction (R-Format), shown in Listing 4. This instruction adds two unsigned 32-bit values stored in the register file under the addresses *rs* and *rt* and stores the result in the register file at the address *rd*.

- **getOpCode:** The operation code is selected by applying right logical shift by the value 26 to the instruction.
- **getFunc:** The function code is determined by logical conjunction, which is applied to the instruction with the hexadecimal value *0x3f*. This

```

let instr := nth instructionMemory pc in
let op := getOpCode instr in
match toFormat op with
| RFormat =>
  let funct := getFunc instr in
  let shamt := getShamt instr in
  let rd := getRD instr in
  let rt := getRT instr in
  let rs := getRS instr in
  match toFunctionCode funct with
  | ADDU =>
    let value := add (nth registerFile rs)
                    (nth registerFile rt) in
    let registerFile' :=
      replaceAt rd value registerFile in
      ((registerFile', memory.newPC pc), value)
  | SLL =>
    let value := sll (nth registerFile rt)
                  (toZ shamt) in
    let registerFile' := replaceAt
      rd value registerFile in
    let pc' := newPC pc in
      ((registerFile', memory.pc'), value)
  [...]
| IFormat =>
  let address := getAddress instr in
  let rt := getRT instr in
  let rs := getRS instr in
  match toOperationCode op with
  | ADDIU =>
    let value := add (nth registerFile rs)
                    address in
    let registerFile' := replaceAt rt value
      registerFile in
      ((registerFile', memory.newPC pc), value)
  [...]
| JFormat => match toOperationCode op with
| J =>
  let tgtadr := getTargetAddress instr in
  let pc' := sll tgtadr z2 in
    ((registerFile', memory.pc'), pc')
  [...]
end

```

Listing 4: Extract of the 32-bit MIPS processor specified using the Coq/ClaSH synthesis flow. It pattern matches over the instructions to access the parts of an instruction as defined by the format.

value represents a bit vector of 26 0s followed by six 1s from the most significant bit (MSB) to the least significant (LSB) (big-endian).

- **getShamt:** The shift amount is selected by first applying right logical shift by the value 6 to the instruction. Afterward, logical conjunction is applied to that value and the hexadecimal value *0x1f*. This value represents a bit vector of 27 0s followed by five 1s, from MSB to LSB (big-endian).
- **getRD:** The destination register is selected by first applying right logical shift by the value 11 to the instruction. Afterward, logical conjunction is applied to that value and the hexadecimal value *0x1f*.
- **getRT:** The first register is selected by first applying right logical shift operation by the value 16 to the instruction. Afterward, logical conjunction is applied, as for the destination register.
- **getRS:** The second register is selected by a right logical shift of the instruction with a shift amount of 21 first. Afterward, logical conjunction is applied, as for the destination register.

```

Theorem mips_addu :
  forall registerFile : registerFileType ,
  forall memory : memoryType ,
  forall pc : Unsigned32.int ,
  forall dummy : bool ,

  let instr := nth instructionMemory pc in
  let op := getOpCode instr in
  let funct := getFunct instr in
  let rd := getRD instr in
  let rt := getRT instr in
  let rs := getRS instr in
  let value := add (nth registerFile rs)
                  (nth registerFile rt) in

  toFormat op = RFormat /\
  toFunctionCode funct = ADDU ->
  mips (registerFile , memory , pc) dummy =
  ((replaceAt rd value registerFile ,
  memory.newPC pc).value).

Proof.
  proveRFormat.
Qed.

```

Listing 5: Theorem specified in Gallina to verify that the ADDU instruction adds the two values of the register addresses (rt and rs) and stores the result at the register file address (rd).

After separating the instruction into its parts as defined by the format, the actual operation can be performed. The *ADDU* instruction defines two register file addresses (rs and rt). The values for these addresses are selected first; *nth registerFile rs* and *nth registerFile rt*. The function *nth* returns a fixed-size vector (registerFile) for a given index (rt). The addition of these two values is stored in the register file at the index *rd* (replaceAt rd value registerFile). The *replaceAt* function replaces a value (value) at an index (rd) of a fixed size vector (registerFile). The final step is to replace the old register file (registerFile) with the changed one (registerFile') and increment the program counter for the next instruction.

4.3 Proving Properties

After the MIPS processor was specified in Gallina, properties can be proven about this specification. Listing 5 shows such a property about the specified *ADDU* instruction, which is defined as a theorem in Coq.

The theorem states that if the operation code (op) indicates the *RFormat* and the function code (funct) indicates the *ADDU* instruction, then the values of the register file addresses *rs* and *rt* are added together. The result is stored in the register file at address *rd*. To verify the final result is calculated correctly, a few statements are defined, starting with the *let* keyword.

Coq's tactic language *L_{tac}* allows the specification of user-defined proof methods (Delahaye, 2000). We specified a proof method called *proveRFormat* that allows proving properties about instructions, which implement the *R-Format* and follow the theorem structure described above. The tactic is seen in Listing 6.

```

Ltac proveRFormat :=
  intros ;
  match goal with
  | [ H : - |- - ] =>
    destruct H as [H1 H2 ] ;
    unfold mips ;
    match goal with
    | [op: - |- - ] =>
      unfold op in H1 ;
      match goal with
      | [instr: - |- - ] =>
        unfold instr in H1 ;
        rewrite H1 ;
        match goal with
        | [funct: - |- - ] =>
          unfold funct in H2 ;
          unfold instr in H2 ;
          rewrite H2 ;
          auto
        end
      end
    end
  end
end.

```

Listing 6: *proveRFormat* tactic in *L_{tac}*. The tactic allows the proving of properties that have the format shown in Listing 5. This format requires splitting the instruction in *op*, *funct*, etc., the instruction format to be *RFormat*, and the specification of the *function code*, e.g., *ADDU*.

The *proveRFormat* tactic is built from tactics already provided by Coq. Coq splits a proof into a context that contains introduced variables, hypotheses, and a goal that is to be proven by the context. The proof is finished if there are no subgoals to prove. The first tactic that is used is the *intros* tactic. This tactic introduces variables, such as *registerFile* or *op* and the hypothesis of the implication. The next step is to match the hypothesis – Coq names the hypothesis with *H* by default. Since the hypothesis is an *and* expression, we destruct it into two hypotheses (H1 and H2) and replace the name *mips* with its specification in the subgoal by calling the *unfold* tactic. The *op* and *instr* variables are unfolded in the hypothesis H1 to rewrite it in the context. This rewriting reduces the subgoal to the second *match* statement (*toFunctionCode funct* seen in Listing 4). The final steps are to unfold the *funct* and *instr* variables in the second hypothesis (H2), applying H2 to the context by the *rewrite* tactic, and finish the proof applying the *auto* tactic. The *auto* tactic tries to automatically solve a goal by introducing new variables and hypotheses to the context and applying built-in tactics to the resulting subgoals. If the *auto* tactic fails, the subgoal remains unchanged. Similarly, proof methods for instructions implementing either the *I-Format* or the *J-Format* were specified.

These proof methods simplify the verification of properties about instructions that have already been implemented and those that might be added in the future. The specification and verification of the theorems for the rest of the instructions work analogously to the one above. Due to size constraints, we cannot show them and the specification of the proof methods

```

Theorem mips_nop:
forall registerFile : registerFileType ,
forall memory : memoryType ,
forall pc output : Types.Unsigned32.int ,
forall dummy : bool ,

let nop := 0x00000000 in

let registerFile' := replaceAt
  (and (srl nop z11) 0xf)
  (sll (nth registerFile
    (and (srl nop z16) 0xf))
    (toInt (and (srl nop z6) 0xf)))
  registerFile in

let output := sll
  (nth registerFile
    (and (srl nop z16) 0xf))
  (toInt (and (srl nop z6) 0xf)) in

  nth instructionMemory pc = nop ->
  mips (registerFile ,memory,pc) dummy =
  ((registerFile' ,memory,newPC pc) ,output) .

```

Listing 7: The NOP instruction is implemented for the MIPS processor as: `sll r0 r0 0`. The value of register `r0` is logically shifted left by 0, and the result is stored in `r0`. The theorem `mips_nop` ensures this behavior. Note that the register `r0` returns the constant zero (MIPS, 2016).

here in detail¹.

After verifying that the specified instructions are correct using the theorem formats and tactics described above, other properties have to be shown that the processor specification is correct and functionally behaves as expected. One of those properties is that the NOP (no operation) instruction is interpreted as specified by the MIPS architecture standard (MIPS, 2016). This instruction does not change any state but only increments the program counter. For the 32-bit MIPS processor NOP is not specified as an extra operation code but maps to the shift logical left operation (SLL), described in Listing 4. The theorem shown in Listing 7 verifies this behavior.

The NOP instruction is a 32-bit vector containing only zeros (0x00000000). This instruction does not change the content of the initial register file, but the SLL operation returns a new register file, as seen in Listing 4. For this reason, the expression `registerFile'` is specified. As the processor interprets the NOP instruction as the SLL operation, the `output` specifies the result of this operation. Note that this theorem cannot be proven using the `proveRFormat` as it does not contain a conjunction in the hypothesis, i.e., it does not follow the required format.

In this section, we have specified and verified a 32-bit MIPS processor using the Coq/C λ SH synthesis flow. The verification of properties successfully addresses the deficiencies of the LegUp synthesis flow, as described in Section 2.2. The specification was automatically synthesized to a Verilog implementation

¹The specification of the 32-bit MIPS processor can be found under: <https://gitlab.informatik.uni-bremen.de/fritjof/mips-processor>

using C λ SH, to answer the question of how the performance of the two implementations compares.

5 EVALUATION

In this section, we evaluate and discuss the performance of both the acceleration-oriented and correctness-oriented synthesis flow. The foundation is the RTL implementation of the 32-bit MIPS processor synthesized by LegUp and Coq/C λ SH. Both implementations implement the same instructions and execute the program, described in Section 2.1. In the following, the results obtained by both implementations are summarized first. Afterwards, we discuss what conclusions can be drawn from that.

5.1 Results

Table 1 shows the performance results of both implementations. The values in this table should be considered an approximation as they highly depend on the FPGA the hardware design is synthesized for; they indicate rather than quantify exactly the relation between the two synthesized designs.

We now explain the individual rows of Table 1 in detail. The first row contains the maximum clock frequency F_{MAX} at which the final circuit can be operated. As we see, the circuit synthesized by the LegUp HLS framework can be operated at a higher frequency than the one synthesized by Coq/C λ SH.

The second row contains the clock cycles needed by the processor implementations to execute the example program (clock latency). These values are evaluated by simulation using Intel[®] Quartus[®] ModelSim. For simulation, a clock cycle of 20 ns was used. Together with the maximum frequency, this results in the time it takes in μ s to execute the program (Wall-Clock) provided by the model, described in Section 2.1. The implementation synthesized by LegUp takes 79.5 μ s for execution, while the implementation synthesized by Coq/C λ SH takes 218.76 μ s.

The fourth row contains the Adaptive Logic Modules (ALMs) called Lookup Tables (LUTs) in the Xilinx Vivado synthesis tool. These are the basic building blocks for hardware designs on an FPGA. As seen, the circuit synthesized by LegUp consumes 2% of the available ALMs, while the one synthesized by Coq/C λ SH consumes 3% of the available ALMs. To better classify these values, we take a look at the last row of the table. This row contains the total block memory in bits, which is essentially the block RAM of the FPGA. The memory of an FPGA

Table 1: Evaluation of the two 32-bit MIPS processor implementations. The *LegUp* column contains the values based on the implementation synthesized by the LegUp HLS framework. The *Coq/ClaSH* column contains the values of the synthesized design based on the Coq/ClaSH synthesis flow used in this work, which is discussed in Section 3.

	LegUp	Coq/ClaSH
F_{MAX} in [MHz]	63.36	55.86
Cycles	5035	12220
Wall-Clock in μs	79.5	218.76
ALMs	1045 / 56480 (2%)	1772 / 56480 (3%)
Registers	939	1644
DSP Block	6 / 156 (4%)	2 / 156 (1%)
Total Block Memory Bits	3072 / 7024640 (< 1%)	0 / 7024640 (0%)

The RTL implementations in Verilog were synthesized for the Cyclone V family using the commercial synthesis tool Intel[®] Quartus[®] Prime.

is separated into distributed RAM (ALMs) and block RAM. LegUp stores each local and global memory in the separated block RAM by default. For larger memories, the block RAM is much faster than distributed RAM. The implementation synthesized by Coq/ClaSH uses no block Ram but stores the entire design in distributed RAM.

The fifth row of Table 1 contains the consumed registers. To classify these values, we consider the design of the 32-bit MIPS processor. The LegUp model of the processor changes the values of an array in place, so only one array, e.g. for the register file, is needed. The functional foundation of the Coq specification and thus the ClaSH model requires *single assignment* of variables. For this reason, the underlying Mealy machine needs the changed register file as part of the new state, as seen in Listing 4. The synthesis of this behavior results in the consumption of more registers.

The sixth row contains the amount of used Digital Signal Processing (DSP) blocks. These blocks describe a dedicated functionality, e.g. multipliers, which are provided by the synthesis tool. The usage of those DSP blocks is automatically inferred by analyzing the RTL code.

5.2 Discussion

In this section, we discuss the results of our evaluation described above. Acceleration-oriented synthesis flows such as LegUp define a model in a hardware DSL embedded into C. The low-level nature of this language allows a more acceleration-oriented implementation of hardware designs, but lacks the verification of properties, as described in Section 2.2.

On the other hand, correctness-oriented synthesis flows such as the Coq/ClaSH flow define a behavior functionally at a higher level of abstraction, making them easier to understand, and hence less error-prone (Hughes, 1989), and susceptible to verification

in the first place. It does, however, have an impact on performance, resulting in lower clock frequency or a higher amount of clock cycles.

Our evaluation shows that although the implementation using the correctness-oriented flow was in general slower than the one using LegUp, we were able to synthesize a 32-bit MIPS processor which is in the *same ball-park* concerning performance indicators like clock frequency or execution time using the standard tool chain of the Coq/ClaSH flow. This systematic comparison shows the huge potential of correctness-oriented synthesis flows, showing that these flows result in circuits with competitive performance.

Research projects like Kami show that the synthesis of verified specifications is a subject of current research. The successful synthesis of a RISC-V processor shows the potential of correctness-oriented flows (Choi et al., 2017). When hardware is used in safety-critical systems, verifying the correct functional behavior becomes essential; our evaluation demonstrates that correctness-oriented flows can achieve this without sacrificing too much performance. Moreover, there is still a huge unexplored potential for performance gains in correctness-oriented flows, whereas adding verification to an acceleration-oriented flow seems, at first sight, far more challenging.

For these reasons, our analysis suggests that correctness-oriented synthesis flows can be employed when the need for verification arises in a performance-oriented environment.

6 CONCLUSION

In this work, we analyzed the acceleration-oriented hardware design synthesis flows as implemented by Bambu (Pilato and Ferrandi, 2013), DWARV (Nane et al., 2012), and LegUp (Canis et al., 2013) and

showed their missing ability of property verification. In contrast, we considered correctness-oriented hardware design synthesis flows, as implemented by Kami (Choi et al., 2017) or the Coq/C λ aSH synthesis flow (Bornebusch et al., 2020). We address the question of a quantitative analysis of the trade-off concerning the performance between both flows by comparing a non-trivial circuit designed by two representative flows. The designed circuit was a synthesized RTL implementation of a 32-bit MIPS processor (Hara et al., 2009). LegUp was chosen as a representative of the acceleration-oriented synthesis flows, while the Coq/C λ aSH flow was chosen as a representative of the correctness-oriented flows.

Our evaluation, seen in Table 1, allows a quantitative analysis of the trade-off between performance and correctness. This paper indicates that using a hardware design flow allowing correctness proofs does not require sacrificing much performance in the implemented system. However, if more performance is needed we argue that it is easier to increase the performance of circuits synthesized by correctness-oriented flows than to add correctness to acceleration-oriented flows. For this reason, we suggest further research to enhance the performance of correctness-oriented flows.

Besides the MIPS instruction set architecture the open RISC-V instruction architecture set (RISC-V, 2020) has got a lot of attention over the last decade. For example, Kami provides a verified 32-bit RISC-V processor that implements the integer instruction set. It would be interesting how the Coq/C λ aSH approach compares to the low-level implementation synthesized by Kami concerning performance. This comparison, however, would be future work as it is outside the scope of this work.
